Abstract

Consider two orthogonal closed chains on a cylinder. The chains are monotone with respect to the angle $\Theta$. We wish to rigidly move one chain so that the total area between the two chains is minimized. This is a geometric measure of similarity between two repeating melodies proposed by Ó Maimín. We present an $O(n)$ time algorithm to compute this measure if $\Theta$ is not allowed to vary, and an $O(n^2 \log n)$ time algorithm for unrestricted rigid motions on the surface of the cylinder.

1 Introduction

We have all heard numerous melodies, whether they come from commercial jingles, jazz ballads, operatic aria, or any of a variety of different sources. How a human detects similarities in melodies has been studied extensively [11, 7]. There has also been some effort in modeling melodies so that similarities can be detected algorithmically. Some results in this fascinating study of musical perception and computation can be found in a collection edited by Hewlett and Selfridge-Field [6].

Similarity measures for melodies find application in content-based retrieval methods for large music databases such as query by humming (QBH) [5, 12] but also in other diverse applications such as helping prove music copyright infringement [3]. Previous work on melodic similarity is based on methods like approximate string-matching algorithms [1, 8], hierarchical correlation functions [9] and two-dimensional augmented suffix trees [2].

Ó Maimín [10] proposed a geometric measure of the distance between two melodies, $M_a$ and $M_b$. The melodies are modelled as monotonic pitch-duration rectilinear functions of time as depicted in Figure 1. Ó Maimín measures the distance between the two melodies by the area between the two polygonal chains. This rectilinear representation of a melody is equivalent to the triplet melody representation in [9].

In a more general setting such as music retrieval systems, we may consider matching a short query melody against a larger stored melody. Furthermore, the query may be presented in a different key (transposed in the vertical direction) and in a different tempo (scaled linearly in the horizontal direction). Francu and Neville-Manning [4] compute the minimum area between two such chains, taken over all possible transpositions. They do this for a constant number of pitch values and scaling factors, and each chain is divided into $m$ and $n$ equal time-steps. They claim (without describing in detail) that their algorithm takes $O(nm)$ time, where $n$ and $m$ are the number of unit time-steps in each query. This time bound can be achieved with a brute-force approach. In this paper we solve a similar problem, in a more general setting.

In some music domains such as Indian classical music, Balinese gamelan music and African music, the melodies are cyclic, i.e. they repeat over and over. In Indian music these cyclic melodies are called tulas [13]. Two such monophonic melodies may be represented by orthogonal
polygonal chains on the surface of a cylinder, as shown in Figure 2. This is similar to Thomas Edison’s cylinder phonographs, where a melody repeats after the cylinder has rotated $2\pi$ degrees. We consider the problem of computing the minimum area between two such chains of size $n$, over all translations on the surface of the cylinder.

We present two algorithms to find the minimum area between two given orthogonal melodies with periods of $2\pi$. The first algorithm will assume that the $\theta$ direction is fixed. The second algorithm will find the minimum area when both the $z$ and $\theta$ relative positions may be varied. We will assume that the vertices defining $M_a$ and $M_b$ are given in the order in which they appear in the melodies.

2 Minimization with respect to $z$ direction

In the first algorithm, we will assume that both melodies are fixed in the $\theta$ direction. Without loss of generality, we will assume that melody $M_a$ is fixed in both directions, so all motion is relative to $M_a$. In Figure 1 we show the area between two melodies, and a small shift of $M_b$ in the $z$ direction.

To see how the area between the two melodies changes as $M_b$ moves in the $z$ direction, consider a set of lines defined by all vertical segments of the melodies as shown in Figure 3. This set of lines partitions the area between the melodies into quadrangles $C_i$, $i = 1, \ldots, k$, defined by two vertical lines and two horizontal segments, one from each melody. Note that $k$ is at most $\frac{n}{2}$. If $M_b$ starts completely below $M_a$, then as $M_b$ moves in the positive $z$ direction, the lower horizontal segment (from $M_b$) will approach the upper fixed horizontal segment while the area of $C_i$ decreases linearly until the horizontal segments are coincident (when this occurs, the area of $C_i$ is zero). Then the upper horizontal segment (now from $M_b$) will move away from the lower fixed horizontal segment while the area of $C_i$ increases linearly. We will consider the vertical position of $M_b$ to be the $z$-coordinate of its first edge. When this edge overlaps the first edge of $M_a$, we have $z = 0$. Let $A_i(z)$ denote the area of $C_i$ as a function of $z$. At $z_i$, $A_i(z_i) = 0$. These $k$ positions of $M_b$ where an $A_i(z)$ is zero will be called $z$-events. The slope of $A_i(z)$ is determined by the length of the horizontal segments of $C_i$. The total area between $M_a$ and $M_b$ is given by $A(z) = \sum_{i=1}^{k} A_i(z)$. Note that since $A(z)$ is the sum of piecewise-linear convex functions, it too is piecewise-linear and convex. Furthermore its minimum must occur at a $z$-event.

**Theorem 1.** A minimum for $A(z)$ can be computed in $O(n)$ time.

**Proof.** The function $A(z)$ is given by $A(z) = \sum w_i |z_{bi} - z_{ai}|$, where $z_{ai}$ is the vertical coordinate of $M_b$ in $C_i$, $z_{ai}$ corresponds to $M_a$, and $w_i$ is the weight (width) of $C_i$, as shown in Figure 3. Let $\alpha_i$ denote the vertical offset of each horizontal segment in $M_b$ from $z_{bi}$. Thus we have $z_{ai} = z_{bi} + \alpha_i$, and $A(z) = \sum w_i |z_{bi} - (z_{ai} - \alpha_i)|$. Finally, notice that the term $z_{ai} - \alpha_i$ is equal to $z_i$. Thus we obtain $A(z) = \sum w_i |z_i - z_{bi}|$. This is a weighted sum of distances from $z_{bi}$ to all the $z$-events. The minimum is the weighted univariate median of all $z_i$ and can be found in $O(n)$ time [14]. This median is the vertical coordinate that $z_{ai}$ must have so that $A(z)$ is minimized. Once this is done, it is straightforward to compute the sum of areas in linear time. 

$\blacksquare$
3 Minimization with respect to $z$ and $\Theta$ directions

If no vertical segments among $M_a$ and $M_b$ share the same $\Theta$ coordinate, then $M_b$ may be shifted in at least one of the two directions $\pm \Theta$ so that the sum of areas does not increase. This means that in order to find the global minimum, the only $\Theta$ coordinates that need to be considered are those where two vertical segments coincide. Thus our first algorithm may be applied $O(n^2)$ times to find the global minimum in a total of $O(n^3)$ time.

We now propose a different approach to improve this time complexity.

As described in the previous section, for a given $\Theta$, the area minimization resembles the computation of a weighted univariate median. When we shift $M_b$ by $\Delta \Theta$, we are essentially changing the input weights to this median. Some $C_i$ grow in width, some become narrower, and some stay the same width. As we keep shifting, at $\Theta$ coordinates where vertical segments coincide, we have the destruction of a $C_i$ and creation of another $C_i$. An important observation is that the rate at which the changing $C_i$ grow or shrink is unique at any given instant.

Let us store the $z$-events and their weights in the leaves of a balanced binary search tree. Each leaf represents one $C_i$. The leaves are ordered by the value $z_i$. Each leaf also has a label to distinguish between $C_i$ that are growing, shrinking, or unaffected when $M_b$ is shifted in the positive $\Theta$ direction. At every node with subtree $T$ we store:

- $G_T$: The number of leaves in $T$ that represent growing $C_i$.
- $W_T^+ = \sum w_i$: The sum of weights over such leaves.
- $S_T$: The number of leaves in $T$ that represent shrinking $C_i$.
- $W_T^- = \sum w_i$: The sum of weights over such leaves.
- $W_T^0 = \sum w_i$: The sum of weights of the remaining leaves in $T$.

This allows us to calculate the weighted median of all $z_i$, by traversing the tree from root to leaf, always choosing the path that balances the total weight on both sides of the path. The time for this is $O(\log n)$.

Suppose that we shift $M_b$ by some offset $\Delta \Theta$, which is small enough such that no vertical segments overlap during the shift. Each $w_i$ that contributes to $W^+$ must be increased by $\Delta \Theta$, and each $w_i$ that contributes to $W^-$ must decrease by this amount. Instead of actually updating all our inputs, we just maintain a global variable representing the total offset in the $\Theta$ direction.

The total weight of a subtree $T$ is now given by $W_T^+ + \Delta \Theta \sum w_i + W_T^- - S_T \Delta \Theta + W_T^0$.

When we shift to a point that two vertical segments share the same $\Theta$ coordinate, we potentially eliminate some $C_i$, create a new $C_i$, or change type of $C_i$. There is only a constant number of such events at each critical $\Theta$ coordinate. The weight given to a created leaf must equal $-\Delta \Theta$. Each of these events involves $O(\log n)$ work to update the information stored in the ancestors of a newly inserted/deleted/aliased leaf. There are $O(n^2)$ such instances where this must be done and where the median must be recomputed, so the total time to compute all candidate positions of $M_b$ is $O(n^2 \log n)$.

At every $\Theta$ coordinate where we recalculate the median, we also need to calculate the integral of area between the two melodies. For a given median $z^*$, the area summation for those $C_i$ for which $z > z_i$ has the form $\sum w_i(z_* - z_i)$.

This may be calculated in $O(\log n)$ time if we know the value of this summation for every subtree. In order
to do this, we store some additional information at every node in our tree. Specifically, if we just consider the contribution to this sum from leaves representing growing $C_i$, we have $\sum (w_i + \Delta \Theta)(z_+ - z_\downarrow)$. For a subtree $T$, this becomes $z_\downarrow w_\downarrow + z_\uparrow \Delta \Theta - \sum w_i z_i - \Delta \Theta \sum z_i$. We see that the additional information that we must store is $\sum w_i z_i$ and $\sum z_i$. To handle shrinking weights, we must also store these two summations taken over the shrinking $C_i$ belonging to $T$. For unaffected weights, we just need $\sum z_i$. All of these stored values may be updated in $O(\log n)$ time when inserting/deleting leaves in the tree. We must also perform this calculation for all $z$-events greater than $z^\ast$.

Since at every critical $\Theta$ position we can calculate the median and integral of area in $O(\log n)$ time, we obtain the following theorem:

**Theorem 2.** Given two orthogonal periodic melodies of size $n$, an relative placement such that the area between the melodies is minimized can be computed in $O(n^2 \log n)$ time.

4 Remarks

A special case of the general problem is to match two melodies while varying only $\Theta$. This problem seems to be just as difficult as global matching. Extensions may involve more complicated representations such as piecewise-linear pitch, the use of integer weights/heights, or the consideration of scaling.
